AMPK (AMP-activated protein kinase) pathway: a potential therapeutic target in cardiometabolic disease

Aaron K. F. Wong, Jacqueline Howie, John R. Petrie and Chim C. Lang
Division of Medicine and Therapeutics, University of Dundee and Medical School, Ninewells Hospital, Dundee DD1 9SY, Scotland, U.K.

Abstract
AMPK (AMP-activated protein kinase) is a heterotrimetric enzyme that is expressed in many tissues, including the heart and vasculature, and plays a central role in the regulation of energy homoeostasis. It is activated in response to stresses that lead to an increase in the cellular AMP/ATP ratio caused either by inhibition of ATP production (i.e. anoxia or ischaemia) or by accelerating ATP consumption (i.e. muscle contraction or fasting). In the heart, AMPK activity increases during ischaemia and functions to sustain ATP, cardiac function and myocardial viability. There is increasing evidence that AMPK is implicated in the pathophysiology of cardiovascular and metabolic diseases. A principle mode of AMPK activation is phosphorylation by upstream kinases [e.g. LKB1 and CaMK (Ca\(^{2+}\)/calmodulin-dependent protein kinase], which leads to direct effects on tissues and phosphorylation of various downstream kinases [e.g. eEF2 (eukaryotic elongation factor 2) kinase and p70 S6 kinase]. These upstream and downstream kinases of AMPK have fundamental roles in glucose metabolism, fatty acid oxidation, protein synthesis and tumour suppression; consequently, they have been implicated in cardiac ischaemia, arrhythmias and hypertrophy. Recent mechanistic studies have shown that AMPK has an important role in the mechanism of action of MF (metformin), TDZs (thiazolidinediones) and statins. Increased understanding of the beneficial effects of AMPK activation provides the rationale for targeting AMPK in the development of new therapeutic strategies for cardiometabolic disease.

Introduction
The prevalence of cardiometabolic diseases is reaching epidemic proportions in industrialized nations and in developing countries [1–3]. Despite aggressive treatment of the individual cardiometabolic risk factors, death from cardiometabolic conditions remains unacceptably high. Therefore there is an urgent need to identify new strategies for treating and preventing cardiometabolic diseases. In this respect, the AMPK (AMP-activated...
protein kinase) pathway has become the focus of a great deal of attention as a novel therapeutic target in cardiometabolic disease because it has been demonstrated to mediate, at least in part, the effects of a number of physiological and pharmacological factors that exert beneficial effects on the vasculature and the heart. AMPK has several important metabolic effects, including increasing muscle glucose uptake [4,5] and ameliorating insulin resistance [6]. It regulates cardiac muscle glucose and lipid metabolism both directly and indirectly in order to provide ATP in response to energy depletion (specifically a rise in the AMP/ATP ratio). AMPK activity can also be modulated by hormones and adipocytokines which may have protective effects against cardiovascular disease. AMPK has also been shown to regulate transcription of genes involved in lipid and glucose metabolism [7,8]. Dysregulation of this process (for example in obesity) can lead to the development of insulin resistance and dyslipidaemia, both of which are major risks factors for CVD (cardiovascular disease). Thus the identification of a compound that specifically and safely activates the AMPK pathway might contribute significantly to the treatment, management and even prevention of CVD. The aim of the present review is to discuss the direct and indirect role of AMPK in normal cardiac physiology and in cardiometabolic disease, and therapeutic strategies in modulating APMK activity.

**STRUCTURE AND REGULATION OF AMPK**

Understanding of the role of AMPK in key physiological pathways has increased several fold in recent years. Its discovery can be traced back to two independent findings reported in 1973 that observed that crude preparations of ACC (acetyl-CoA carboxylase) [9] and HMG-CoA (3-hydroxy-3-methylglutaryl-CoA) reductase [9a] became inactivated when incubated with ATP. Both groups predicted that the effects were due to phosphorylation of the enzymes by an endogenous protein kinase that contaminated their preparations. It was subsequently shown that this protein kinase was itself activated by phosphorylation by an upstream kinase [10]. In 1987, Carling et al. [11] made the discovery that the inactivation of ACC and HMG-CoA reductase were both catalysed by a single protein kinase. As it became clear that it was a true multi-substrate kinase, they renamed it AMP-activated protein kinase after its allosteric activator 5'-AMP [12]. Hardie [13] has described AMPK as a ‘fuel gauge’ and ‘guardian of energy status’, implying the fundamental role of AMPK in energy metabolism and maintaining body energy balance. AMPK is a heterotrimeric enzyme complex which consists of α, β and γ subunits, each of which has two or more isoforms that are encoded by distinct genes and are differentially expressed in various tissues. The α subunit contains the catalytic domain, including the important regulatory Thr172 residue, which is phosphorylated by upstream kinases. The β subunit has glycogen-binding C-terminal domains that are sufficient on their own to form a complex with the α and γ subunits. High cellular glycogen content exerts an inhibitory effect on AMPK through an interaction with the β subunit in skeletal muscle, although the exact mechanism is unknown [14]. The γ subunit of AMPK was first recognized by Bateman [15] and contains four repeats forming two domains. Each of these domains binds one molecule of AMP or ATP ion in a mutually exclusive manner [16], consistent with the findings that high concentrations of ATP antagonize activation of AMPK by AMP.

For many years, the upstream kinase(s) that phosphorlates Thr172 on the α subunit of AMPK remained unidentified. In recent years, it has been established that the major upstream kinase in mammalian cells is a complex of the protein kinase LKB1 and two accessory subunits STRAD (Ste20-related adaptor) and MO25 (mouse protein 25) [17–19]. LKB1 also acts as an upstream kinase of at least 12 other AMPK-related kinases [20,21]. It has also been found to be a tumour suppressor and was identified in humans as a gene carrying an autosomal-dominant mutation in Peutz–Jeghers syndrome [19,22]. The STRAD subunit is essential for the ability of the LKB1 complex to phosphorylate Thr172 on AMPK [18]. Besides LKB1, STRAD and MO25, AMPK can also be activated by an LKB1-independent mechanism involving CaMKs (Ca²⁺/calmodulin-dependent protein kinases).

AMPK exerts its metabolic effects through its interactions with various metabolic pathways. Activation of these metabolic pathways via AMPK activation leads to remodelling of various components of the metabolic syndrome [23] (Figure 1). AMPK plays a major role in providing ATP in the midst of energy depletion via its interactions with various metabolic pathways (Figure 2). Furthermore, AMPK also has direct and indirect effects on the cardiovascular system, and the understanding of such effects provides the rationale of targeting AMPK as a new therapeutic modality for the treatment and prevention of CVD.

**AMPK: DIRECT EFFECTS ON THE CARDIOVASCULAR SYSTEM**

Congestive cardiac failure, LV (left ventricular) hypertrophy, myocardial ischaemia and diabetic cardiomyopathy are all associated with disturbances of cardiac energy homeostasis. In these pathological states, AMPK activity is up-regulated in response to an increased AMP/ATP ratio (energy-depleted state). AMPK switches on energy-generating pathways to increase cardiac myocyte fatty acid uptake [24] and increase glucose uptake by increasing the translocation of GLUT-4 (glucose transporter-4) in a P13K (phosphoinositide

AMPK pathway as a potential therapeutic target in cardiometabolic disease

AMPK and cardiometabolic disease

During cardiometabolic disease, the AMP/ATP ratio is increased as a result of decreased oxidative metabolism of both NEFAs (non-esterified fatty acids) and glucose due to diminished oxygen supply and increased glycolytic ATP production and glucose transport [28]. Russell et al. [5] have shown that AMPK activation using AICAR (5-aminono-4-imidazole-carboxamide riboside-1-β-D-ribofuranoside) in an in vitro rat model increased translocation of glucose transporters (i.e., GLUT-4) into the sarcolemma and, hence, increased glucose uptake. Furthermore, AMPK also phosphorylates and activates PFK-2, leading to the production of fructose 2,6-bisphosphate, a potent stimulator of glycolysis. AMPK may be necessary for adiponectin to exert its cardioprotective effect against ischaemia/perfusion injury [29]. Both the α1 and α2 subunits of AMPK are activated during myocardial ischaemia, with the α2 subunit being activated to a greater extent [30,31].

Previous studies in transgenic mice have shown that decreased α2 activity resulted in reduced cardiac glucose uptake following ischaemia [32] and impaired recovery of LV systolic function [31]. Additionally, in transgenic mice expressing a kinase-dead form of the enzyme, phosphocreatinine was also lower after reperfusion [31]. These observations suggest that activation of AMPK following ischaemia has a cardioprotective effect and results in lesser cardiac injury and faster recovery. Calvert et al. [33] have also shown that activation of AMPK with MF (metformin) resulted in decreased myocardial injury in both diabetic and non-diabetic mice. This may be a result of deriving ATP from more energy-efficient glucose metabolism from increased AMPK-mediated glucose uptake and glycolytic flux in the face of oxygen deprivation [34,35].

However, ischaemic-induced activation of AMPK may be detrimental to the ischaemic heart, as suggested by Dyck and Lopaschuk [36]. During ischaemia, circulating fatty acid levels are elevated [37], which may be detrimental to the ischaemic heart [38,39]. Activation of AMPK leads to increased fatty acid uptake and inhibition of malonyl-CoA, a potent endogenous inhibitor of mitochondrial fatty acid uptake. This results in accelerated mitochondrial fatty acid uptake and, hence, increased mitochondrial acetyl-CoA production from β-oxidation. High levels of acetyl-CoA have an inhibitory effect on PDH (pyruvate dehydrogenase), reducing the amount of pyruvate being converted into acetyl-CoA and, hence, reduced glucose oxidation (the...
AMPK and cardiac arrhythmias

Mutations of the γ2 subunit of AMPK have also been shown to contribute to glycogen storage disease and Wolff–Parkinson–White syndrome [40]. Gollob et al. [40] identified in 2001 a mutation (Arg531Gly) in the AMPK γ2 subunit (PRKAG2 gene) to be responsible for Wolff–Parkinson–White Syndrome and early onset of atrial fibrillation and conduction disease. Using a transgenic model targeting the murine gene, Davies et al. [41] demonstrated striking cardiac manifestations, such as hypertrophy, impaired contractile function, electrical conduction abnormalities and marked glycogen accumulation. Furthermore, Sidhu et al. [42] have identified a
distinct atrial ventricular accessory pathway and a prolonged QRS in this transgenic mice model. However, the effects of the mutations described in this gene on the overall activity of AMPK varies in the different experimental models [43,44]. It is still uncertain whether these cardiac manifestations are the result of disease-causing mutations or secondary to glycogen deposition. Murphy et al. [45] postulated that the manifestations of AMPK disease may be due to defects in energy utilization or in specific cellular substrates, rather than mere passive deposition of glycogen. Nonetheless, these findings illustrate an important role for AMPK in cardiac hypertrophy and arrhythmias.

**AMPK and cardiac hypertrophy, cell growth and gene transcription**

AMPK may play a further role in the regulation of normal cardiac cell growth [31,32] and energy regulation in the hypertrophied heart [46], via its effects on protein synthesis [47,48]. Mutations in $\gamma_2$ subunits not only cause glycogen overload in the heart and Wolff–Parkinson–White syndrome, but also hypertrophy and HF (heart failure) [40,49–51]. The severity of the defect also correlates with the severity of the disease. eEF2 is the main mediator of the translocation step in protein synthesis and is inhibited through phosphorylation of eEF2 kinase. p70S6K regulates protein synthesis through the same pathway or via phosphorylation of ribosomal protein S6. Chan et al. [48] have shown that AMPK not only regulates eEF2 kinase, but also exerts effects on protein synthesis via the mTOR pathway, ultimately leading to inhibition of p70S6K. Furthermore, Chan et al. [48] have shown that activation of AMPK using MF and AICAR results in inhibition of protein synthesis, and is associated with prevention and regression of cardiac hypertrophy. However, studies in transgenic mice have shown that elevated AMPK activity is associated with the accumulation of large amounts of glycogen, leading to dramatic LV hypertrophy and arrhythmias [46,52]. It remains uncertain, therefore, whether AMPK activation in the hypertrophied heart is beneficial [48,53] or deleterious, and further studies are required.

**AMPK and vascular and endothelial function**

AMPK also plays an important role in the regulation of vascular function and structure. It activates eNOS (endothelial NO synthase) in endothelial cells and cardiac myocytes by phosphorylation at Ser1177 (human sequence) [54,55]. eNOS activation leads to augmentation of vascular tone, platelet aggregation, leucocyte adherence and vascular smooth muscle proliferation [56].

Using a diabetic rat model, Suzuki et al. [57] have shown that activation of AMPK using a cAMP phosphodiesterase inhibitor, cilostazol, restores endothelial function independently of cAMP. Administration of cilostazol leads to phosphorylation of AMPK and subsequent phosphorylation of eNOS and increased NO production. Other AMPK activators, AICAR [58], MF [59] and rosiglitazone [60], have all been shown to increase NO production in human aortic endothelial cells via the AMPK pathway. Additionally, AMPK also appears to have a role in angiogenesis, promoting the action of the HIF-1α (hypoxia-inducible factor-1α)/VEGF (vascular endothelial growth factor) pathway [61,62], and inhibiting AngII (angiotensin II)-induced smooth muscle cell proliferation [63]. Furthermore, activation of AMPK using AICAR has been shown to inhibit palmitate-induced endothelial cell apoptosis through suppression of ROS (reactive oxygen species) [64]. It is clear that AMPK plays a central role in vascular biology.

**AMPK: INDIRECT EFFECTS ON THE CARDIOVASCULAR SYSTEM**

Recent findings have shown that levels of adipocytokines such as adiponectin and leptin correlate with the development of different components of the metabolic syndrome [65]. AMPK has been suggested to play a role in mediating the metabolic and vascular effects of the key adipocytokines [66,67].

**AMPK and leptin**

Leptin is an adipocyte-secreted hormone that plays a pivotal role in the regulation of food intake, energy expenditure, body weight and neuroendocrine function [68]. Leptin stimulates fatty acid oxidation [69] and glucose uptake [70], and prevents lipid accumulation outwith adipose tissue, preventing lipotoxicity [71]. Deposition of ectopic fat in pancreatic β-cells, myocardium and skeletal muscle contributes to the pathogenesis of Type 2 diabetes mellitus, cardiomyopathy and insulin resistance respectively. Leptin is known to exert its effects via the AMPK pathway, stimulating phosphorylation and activation of the $\alpha_2$ catalytic subunit of AMPK selectively in skeletal muscle [69]. Leptin also suppresses ACC2 activity, thereby stimulating fatty acid oxidation in muscle. AMPK also inhibits lipogenesis and ectopic fat deposition in the liver [72]. AMPK is also a key regulator of leptin action in the hypothalamus and a ‘master regulator’ of food intake. Minokoshi et al. [73] have shown that inhibition of AMPK activity by leptin specifically in the arcuate and paraventricular nuclei is essential for its anorexigenic and weight-loss effects.

**AMPK and adiponectin**

Adiponectin, an adipose-specific protein present in high concentrations in the circulation, was first identified in 1996. It possesses anti-atherogenic, insulin-sensitizing and anti-inflammatory properties. Yamauchi et al. [66]
have shown that adiponectin stimulates glucose utilization and fatty acid oxidation via the AMPK pathway. Furthermore, adiponectin has been shown to reduce infarct size, improve LV function and remodelling, and increase coronary flow during reperfusion in animal models. The underlying mechanisms are thought to be phosphorylation of eNOS, AMPK Thr172 and Akt Ser473 [74]. Adiponectin-deficient mice have been shown to have progressive cardiac remodelling in a pressure-overloaded setting, particularly in experiments relating to glucose metabolism, insulin signalling pathways and lipid metabolism [75]. Therefore the AMPK pathway is not only critical for the metabolic and insulin-sensitizing actions of adiponectin, but also its cardioprotective effects in myocardial ischaemia and reperfusion.

**AMPK ACTIVATORS: PHARMACOLOGICAL TOOLS AND THERAPEUTIC POTENTIAL**

As we have seen above, AMPK is a pivotal enzyme that regulates diverse signals in metabolic pathways and has direct and indirect effects on the heart and vasculature. AMPK activation has not only been shown to alleviate various components of the metabolic syndrome, but may also improve LV hypertrophy and reduce cardiac injury in ischaemia. AMPK is also a key mediator of the anti-atherosclerotic and insulin-sensitizing effects of adiponectin. Therefore it is clearly an attractive therapeutic target in cardiometabolic disease. A number of AMPK activators are available as pharmacological tools and some are in clinical use (Table 1).

**AICAR**

AICAR is an adenosine analogue which activates AMPK through direct binding, followed by allosteric modification. It is initially taken up by adenosine transporters and subsequently phosphorylated to ZMP (5-aminoimidazole-4-carboxamide-1-β-d-furanosyl 5'-monophosphate) within the cell, which mimics AMP in AMPK signalling [76]. AICAR was first developed to block adenosine reuptake in the ischaemic heart, promoting stimulation of adenosine membrane receptors. In 1997, treatment with acadesine (AICAR) before and during surgery was shown to reduce early cardiac death, MI and combined adverse cardiovascular outcomes [77], although the mode of action via AMPK was not fully appreciated at that time.

AICAR is now widely used in the laboratory setting, particularly in experiments relating to glucose metabolism, insulin signalling pathways and lipid metabolism. In recent years, AICAR has been shown to reverse various aspects of the metabolic syndrome in animal models [23,78–80] and healthy human subjects [81] (Table 2). AICAR has also been shown to stimulate adiponectin and inhibit cytokines, such as TNF-α (tumour necrosis factor-α) and IL-6 (interleukin-6), which have been implicated in the development of obesity-induced insulin resistance [82–85]. Unfortunately, AICAR is far from an ideal activator of the

AMPK pathway in the clinical settings because of its short half-life, requirement for intravenous infusion and variable effectiveness. It also causes bradycardia and can lead to hypoglycaemia when administered intravenously. Therefore there is great interest in developing a more potent, safer and more specific activator.

**Metformin**

MF has been used to treat diabetes for more than 50 years and is associated in observational studies with reduced mortality and improved outcomes in patients with CHF (chronic HF) [86,87]. It is the preferred antidiabetic medication for obese patients with Type 2 diabetes mellitus and HF. This wide spectrum of cardiovascular effects in a recent study via its indirect AMPK activation [96]. However, the precise mechanisms of how MF activates AMPK are still poorly understood.

Even though MF is regarded as an AMPK activator, it has not been shown to bind directly to AMPK; neither does it regulate its own phosphorylation and dephosphorylation in cell-free assays [97]. One hypothesis is that it activates AMPK by inhibiting Complex I of the respiratory chain, which subsequently causes an increase in the AMP/ATP ratio [98,99]. In fact, inhibition of the respiratory chain in the intestinal mucosa may account for the gastrointestinal side effects of the drug, and this property may account for the propensity of its predecessor biguanides phenformin to cause lactic acidosis. MF is transported into intestinal cells mainly by OCT-1 (organic cation transporter-1), but phenformin penetrates cell membranes without active transport. Identification of polymorphisms in genes encoding cation transporter proteins may ultimately explain differences in tolerance and response to MF [100]. Interestingly, there are also studies suggesting that AMPK can be activated by MF without changes in the AMP/ATP ratio [97,101], and MF can also exert its beneficial metabolic effects on cardiac myocytes in an AMPK-independent manner [102].

However, we should be mindful that extra caution is required if we are to use these results to extrapolate to the effects of MF on AMPK. First, variable doses of MF have been used in these studies. The plasma MF concentration in clinical use is usually approx. 10 μmol/l [103], whereas the doses used in *in vivo* and *in vitro* experiments are consistently higher, in the range of 1–10 mmol/l (Table 3). Saeedi et al. [102] have shown that lower doses of MF (i.e. 2 mmol/l) failed to activate AMPK and caused no

changes in energetic state. On the contrary, Hawley et al. [97] have shown that lower doses of MF can actually produce AMPK activation without a significant change in the cellular AMP/ATP ratio. Other research groups have reported that AMPK activation required higher doses of MF (i.e. 5–10 mmol/l) [89,91] (Table 3) and suggested that higher doses of MF are required to cause changes in the energetic state and, hence, subsequent AMPK activation. However, these divergent results may be the result of different exposure time of MF. For instance, Yang and Holman [90] have shown that a lower dose of MF (1 mmol/l) activated AMPK and increased cardiac myocyte glucose uptake after a prolonged exposure of 18 h. On the other hand, Bertrand et al. [104] have shown that short exposure (4 h) of MF can result in AMPK activation if much higher doses of MF were used (5–10 mmol/l). Therefore AMPK can be activated by MF in a time- and concentration-dependent manner. Clearly further studies are required to determine the time and concentration of MF which will result in the maximal beneficial effects of AMPK activation without intolerable side effects.

### TZDs (thiazolinediones)

TZDs (i.e. rosiglitazone and pioglitazone) are ligands for the nuclear hormone receptor family member PPAR-γ (peroxisome-proliferator-activated receptor-γ) [105]. Both rosiglitazone and pioglitazone have been shown to activate AMPK in intact cells [106,107]. TZDs can also activate AMPK by stimulating the release and expression of circulating adiponectin from adipose tissue [66,67] or indirectly by increasing the cellular AMP/ATP ratio, possibly by a similar mechanism to biguanides [108]. Both rosiglitazone and pioglitazone have been suggested to have additional and protective beneficial anti-atherosclerotic and anti-inflammatory effects [109]. Furthermore, TZDs have also been shown to have diverse beneficial effects on endothelial function, TNF-α, NO
and endothelial cell proliferation via AMPK-dependent and PPAR-γ-independent mechanisms [110–114]. These effects may translate into an improvement in clinical outcomes in patients with cardiometabolic disease. Previous studies have raised the intriguing possibilities that these effects may be mediated via AMPK activation [107,115,116]. However, as with MF, we are not certain whether AMPK activation is the key to these beneficial clinical effects on cardiovascular system. Furthermore, we also need to be very cautious when we try to translate these observations in animal studies to the clinical setting. The doses and type of TZDs that have been shown to activate AMPK vary among different research groups and the doses used in these animal studies may not be applicable to human subjects. Furthermore, the majority of these in vivo studies are short-term studies examining the effects of acute AMPK activation and its metabolic effects; however, the effects of long-term AMPK activation by TZDs have yet to be determined. Nonetheless, the cardiovascular-protective effects of TZDs are evidenced in the recently published post-hoc analysis from the PROactive (PROspective pioglitAzone Clinical Trial In macroVascular Events) study [116]. This showed that patients who have chronic kidney disease and received pioglitazone are less likely to reach composite end points of all-cause death, MI and stroke, independent of the severity of renal impairment.

However, it should be noted that TZD use is associated with the risk of fluid retention which may exacerbate HF [117]. In a recent meta-analysis, Lago et al. [118] reported that TZDs increased the risk of developing CHF, probably as a result of fluid retention, across a wide background of cardiac risk [relative risk, 1.72 (95% confidence interval, 1.21–2.42); P = 0.002]. There is also a concern that these agents may be associated with additional cardiovascular (MI and stroke) risk in patients with Type 2 diabetes mellitus with rosiglitazone. However, it should be noted that these meta-analyses included many small trials [119], whereas large clinical trial data have shown no sign of these cardiovascular events [RECORD (Rosiglitazone Evaluated for Cardiac Outcomes and Regulation of glycemia in Diabetes) and PROactive] [117,120]. The EMEA (European Medicines Evaluation Agency) for Medicinal Products for Human Use has adopted a scientific opinion in January 2008 recommending the inclusion of a new warning stating that the use of rosiglitazone in patients with ischaemic heart disease and/or peripheral arterial disease is not recommended. A recent FDA (Federal Drug Administration) review suggested that more large randomized studies with active comparators should be conducted by the manufacturers.

**Statins**

Statins are widely prescribed in patients with the metabolic syndrome owing to the high incidence of hypercho-

iterelease. However, the compound has poor oral bioavailability, limiting its use in clinical settings.

An alternative small-molecule compound that is safe, potent, acts directly on AMPK and has good oral
bioavailability would be an attractive candidate to progress towards clinical development.

CONCLUSIONS

Activation of the AMPK pathway may be the key in treating and preventing various cardiometabolic diseases; however, it is still uncertain whether direct activation of the AMPK pathway in the absence of a physiological stress will be beneficial or deleterious overall in humans. It is hoped that chronic activation of AMPK will not result in ‘over-compensatory’ activation of other systems such as the RAAS (renin–angiotensin–aldosterone system) activation in HF. Alterations in cardiac AMPK activity are associated with a number of cardiovascular-related diseases, such as pathological cardiac hypertrophy [50], myocardial ischaemia [36], glycogen storage cardiomyopathy [52] and Wolff–Parkinson–White syndrome [51], suggesting a possible maladaptive role in such conditions. Andersson et al. [132] described antisatiation effects of AMPK, which may lead to weight gain. Furthermore, McCullough et al. [133] also demonstrated that activated AMPK may be harmful in stroke. All of these uncertainties will need to be clarified by further translational studies, and much effort is still required to define the roles of AMPK activation in various conditions that have been discussed above. Furthermore, it is also a great challenge for pharmaceutical companies to produce a specific AMPK activator that has predictable effects owing to its heterotrimeric structure and its complex interactions with various upstream and downstream kinases. The other approach in which many researchers have adopted is to develop a compound that targets the downstream kinases of AMPK [i.e. a malonyl-CoA activator or CPT-1 (carnitine palmitoyltransferase-1) activator]. The AMPK/malonyl-CoA/CPT-1 axis might represent an interesting pathway for further research in cardiac substrate utilization and fatty acid metabolism. The AMPK–adipocytokine interaction has also formed the rationale for the development of new treatment modalities for the treatment of obesity. Lastly, AMPK/mTOR/eEF2/p70RSK axis modulation may be the key to understanding the pathogenesis of cardiac myocyte hypertrophy and mitochondrial biogenesis. A greater understanding of the biochemistry and physiology of AMPK and a better understanding of the mechanisms of action of existing agents have nonetheless opened up a new horizon for the treatment and prevention of cardiovascular and metabolic disease.
